ABSTRACT
Avian adenoviruses are an extremely diversified group of pathogens that recently triggering a variety of problems for poultry production. In particular, Inclusion Body Hepatitis-Hydropericardium Syndrome (IBH-HPS), which has been observed in broiler birds from 3 to 6 weeks of age and is associated with anemia, hemorrhagic disorders, hydropericardium, and high mortality. The disease has been reported worldwide, and recently it was reported in many Egyptian farms, causing severe economic losses. Therefore, the current study aimed to isolate, and genetically typing the most common Adenovirus serotypes associated with this syndrome in Egyptian flocks. A total of 50 broiler chicken farms (3-6 weeks old) located in different Egyptian governorates were examined. Macroskopically, the diseased flock revealed hydropericardium, enlarged friable liver with echymotic hemorrhages, and varying mortality rates (1 to 7.5%). Histopathologically, severe diffuse necrotizing enteritis, hepatitis, pericarditis, and diffuse lymphoid depletion of the spleen were the most prominent lesions. Liver tissues and cloacal swabs were collected from all examined flocks for FAdVs detection by conventional polymerase chain reaction (PCR) targeting the L1 loop in the hexon gene. The PCR products were sequenced for typing of the detected viruses. It was found that 10 out of 50 flocks examined were PCR positive for FAdVs (20%). Phylogenetic analysis of the sequenced genes revealed that the obtained viruses clustered with reference strains belonging to FAdV type D and E serotype 2, 11, and 8a respectively. The isolation of both FAdV type D and FAdV type E were carried out on a primary cell culture chicken embryo liver cell (CEL) and the presence of these viruses was confirmed by PCR after the appearance of cytopathic effect (CPE). From this study, it could be concluded that both FAdVs types D and E are the most common adenoviruses circulating in poultry farms suffering from hydropericardium and inclusion body hepatitis.

Keywords: Broiler chicken, Chicken embryo liver cell, Fowl adenovirus, Hexon gene, Histopathology, Inclusion body hepatitis–hydropericardium syndrome, PCR

INTRODUCTION
Adenoviruses (AdVs) belong to the family Adenoviridae which are non-enveloped double-stranded DNA viruses. This family is distributed worldwide and has been recently classified into five genera, including Aviadenovirus, Mastadenovirus, Atadenovirus, Siadenovirus, and Ichtadenovirus (Hess, 2000). Virological analyses have enabled the division of the avianadenoviruses into five species of 12 serotypes (FADV-1 to FADV-8a and FADV-8b to FADV-11) based on genomic restriction digest patterns (FADV-A to FADV-E) (Hess, 2000). It has been shown that hepatitis inclusion body (IBH), hydropericardium syndrome (HPS), and gizzard erosion (GE) are the most common diseases associated with FADV infection in chickens (Mittal et al., 2014) The FAdVs’ 12 serotypes have been associated with IBH outbreaks (Li et al., 2018, Chen et al., 2018). However, FAdVs type D and E including serotypes; FAV-2, -3, -11 and FAV-6, -7, -8a, -8b respectively, are the most common relevant isolates (Schachner et al., 2018a). Recently, outbreaks of IBH-HPS have hit several countries over the globe such as Japan (Nakamura et al., 2011), Malaysia (Mohamed Sohaimi et al., 2019), China (Li et al., 2018), India (Raj et al., 2018; Suohu et al., 2021) Spain (Oliver-Ferrando et al., 2017), Iran (Morshed et al., 2017), South Africa (Maartens et al., 2014) and Saudi Arabia (Hemida and Alhhamadi, 2017). The disease mortalities reach 5-10% and may surge to 30% if it is co-infected with other immunosuppressive agents, such as Chicken infectious anemia virus CIAV and Infectious bursal disease virus (IBDV) (McFerran and Smyth, 2000). Moreover, virulent HPS caused by FAdV serotype 4 (FAdV-4) leads to high mortality varying from 30-70% (Mansoor et al., 2011; Schachner et al., 2018; Khan et al., 2019).

Grossly, the infected broilers revealed lesions in the liver and heart in the form of the enlarged, pale, friable liver with echymotic hemorrhages in addition to the accumulation of straw yellow-colored fluids in the pericardium (Schachner et al., 2018). Histologically, the most common findings were hepatitis, pancreatitis, nephrosis, thymic and bursal atrophy, and lymphoid depletion in the bursa and spleen. Basophilic and eosinophilic inclusion bodies of variable...

appearance were recorded in liver infected with IBH and rarely in the kidney. Moreover, HHS syndrome results in inflammatory and degenerative lesions mainly in the heart, kidneys, lungs, and intestine (Schachner et al., 2018).

Polymerase chain reaction (PCR) using primers specific to L1 loop as the most conserved region in hexon gene is used for characterization of FAdVs. Hexon is the main adenovirus protein and is typically used to detect FAdVs molecularly. Further FAdV typing was carried out using restriction enzyme length polymorphism (RFLP) and/or DNA sequencing (Hess, 2000) in Egypt. FAdVs outbreaks have been reported and confirmed by the sequence analysis of the viruses in collected samples (El-Tholoth and Abou El-Azm, 2019; Radwan et al., 2019; Elbestawy et al., 2020). Therefore, the current study was conducted for isolation, molecular characterization, typing, and histopathological picture of the most recent FAdVs circulating in broiler farms suffering from IBH/HPS in different Egyptian governorates.

MATERIALS AND METHODS

Ethical approval

The procedures for chicken handling were carried out in compliance with the applicable legislation of the Institutional Animal Care and Use Committee of the Faculty of Veterinary Medicine, University of Cairo, Egypt (VetCU24112020261).

Sample collection

The examined farms were in Egypt at Menofya, Menia, Giza, Beheira, and Fayum Governorates during 2019-2020. Liver tissues and cloacal swabs were collected from 50 broiler chicken farms (5 birds from each farm with a total number of 250 birds as 200 freshly dead and 50 birds with severe clinical signs that were euthanized) with the age range of 3-6 weeks for the detection of FAdVs. In addition, the bursa of Fabricius was collected for the detection of IBDV. The pooled cloacal swabs from each farm were dissolved in 1 mL normal saline with a pH of 7.4 containing (1 mg/mL) streptomycin (50 μg/mL) gentamycin and (100,000 IE/mL) penicillin. The liver and bursa tissue samples were collected in phosphate-buffered saline (PBS) then transported to the laboratory in an icebox. All samples were stored at -20 °C for further processing and virus detection. In addition to the tissue specimens that were collected for histopathological examination.

Preparation of collected samples

The collected cloacal swabs samples were centrifuged at 700 × g for 10 minutes to clarify them. The collected supernatant was filtered by 0.2-μm pore size syringe filters. The pooled liver samples (5 from each farm) were ground by sterile mortar and pistol. A 20% (w/v) suspension was prepared using sterile saline solution. Centrifugation of the suspensions was carried out for 20 minutes at 2000 rounds per minute (r.p.m.) Collected supernatants were preserved at -20°C till use. (Radwan et al., 2019)

Histopathology

Tissue specimens from the intestine, liver, heart, and spleen of chickens in suspected farms were fixed in 10% neutral buffered formalin. The tissues were dehydrated, cleared, embedded in paraffin, and sectioned by microtome into 4 μm thick (Suvarna et al., 2018). Tissue sections were stained by hematoxylin and eosin stain, examined by a light microscope, and photographed by a digital camera (Olympus XC30, Tokyo, Japan).

Virus detection and Identification by PCR

Extraction of nucleic acid

The Genomic DNA isolation kit (Genedirex, Cat no. SN026-0100, Taiwan) was used to extract the total viral nucleic acid from 300 μL of the supernatant following the manufacturer’s instructions.

Oligonucleotide primers

In this study, the forward (HexL1-s) and reverse (HexL1-as) primers corresponding to a conserved area in the hexon gene L1 region were used (Raue et al., 2005) and are listed in Table 1.

Polymerase chain reaction

Amplification of the target gene was achieved in a reaction volume of 25 μL containing 5 μL DNA template (congruent to 20% of the total reaction volume), 1 μL of 10 μM forward (HexL1-s) and the same of reverse (HexL1-as) primers, 12.5 μL 2X One PCR™ polymerase chain reaction (PCR) master mix (One PCRTM, Genedirex; Cat. No. MB203-0100), and 5.5 μL nuclease-free water. One initial denaturation cycle of 4 minutes at 94°C was required for the PCR cycling profile, followed by 35 amplification cycles of 45 seconds for denaturation at 94°C, 45 seconds for annealing at 51°C, and 1 minute for the extension at 72°C, and a final extension stage at 72°C for 10 minutes. In 1.5% agarose gel stained with ethidium bromide, the resulted amplified PCR products were electrophoresed and visualized under ultraviolet transillumination.

Sequence and phylogenetic tree analysis

The nucleotide sequence alignment was assembled and analyzed with representative reference to FAdVs strains’ hexon gene sequences obtained from the GenBank database (http://www.ncbi.nlm.nih.gov/) using the NCBI BLAST server to confirm the identity with FAdVs strains. In BioEdit version 7.0.1.4 (Tom Hall, Ibis Biosciences, Carlsbad, CA, USA), sequences of FAdV hexon genes were downloaded from the NCBI GenBank and aligned using the Clustal W program. The subsequent phylogenetic analysis was carried out using Molecular Evolutionary Genetics Analysis version 6.0 constructed by the maximum likelihood approach based on the approximately 590-bp region corresponding to nucleotides 301-890 of the hexon gene and was used to demonstrate the clustering of the discrete species based on their hexon gene sequences. A similarity matrix has been created using the DNASTAR program (Lasergene, version 8.0).

Detection of concurrent infection with infectious bursal disease virus and chicken infectious anemia virus by conventional PCR

Detection of accompanied infections with infectious bursal disease virus (IBDV) and chicken infectious anemia virus (CIAV) was performed using the extracted viral DNA/RNA from the liver for CIAV and bursa of Fabricius tissues for IBDV from Adenovirus positive cases by conventional PCR assay as previously reported by Metwally et al. (2009) and Elbestawy et al. (2020).

Virus isolation on primary chicken embryo liver cells

Virus preparation

The supernatant of the collected FAdVs positive by PCR samples was passed through syringe filters with 0.2-μm pore size. Primary chicken embryo liver (CEL) cell was obtained from the liver of 15-day-old SPF embryonated chicken eggs (ECE) (Kumar et al., 2003).

Virus propagation

Flasks containing complete monolayer were washed two successive times with serum-free medium and inoculated with 0.1mL of the forementioned supernatant. For virus adsorption onto cells the inoculated flasks were incubated at 37°C for one hour then a maintenance medium containing 2% fetal bovine serum (FBS) was added. Daily observation of the inoculated cells for CPE was done using an inverted microscope during the first three successive days post-inoculation (pi). After obvious CPEs development, the flasks were harvested three times by repeated freezing and thawing before centrifugation at 216 x g for 10 minutes. Viral fluid was collected and stored at -20°C for further process. Complete monolayers were prepared for subsequent passage and inoculated with 0.1 mL of viral fluid. However, one monolayer was left uninoculated and was used as control cells (Mansoor et al., 2011).

Confirmation of fowl adenoviruses in cell culture by PCR

After the appearance of CPE in cell culture, the presence of FAdVs was confirmed by conventional PCR.

RESULTS

Clinical cases and gross lesions

During 2019-2020, 50 broiler flocks suffering from hydropericardium IBH syndrome in different governorates in Egypt were examined. The distribution and mortalities are summarized in Table 2 and Figure 1. Clear postmortem lesions in the form of a clear straw yellow serous fluid accumulation in the pericardium, swollen livers with necrotic foci, and petechial hemorrhages were observed (Figure 2).

Histopathological findings

Microscopy of the intestine showed severe diffuse necrotizing enteritis which was either acute or chronic according to the stage of infection. Intranuclear basophilic inclusion bodies were seen in infiltrating cells (Figure 3a, b, c). The hepatic lesions varied from vacuolation and necrobiotic changes to massive necrosis and dissociation of hepatocytes at the periphery of hepatic lobules with the presence of intranuclear eosinophilic inclusion bodies (Figure 3d, e, f). The heart had endothelial cell hypertrophy of blood vessels, pericarditis, degeneration of muscle bundles, necrotic foci with...
mononuclear cells infiltration, edema, heterophils infiltration in between muscle bundles, and perivascular mononuclear cells infiltration in addition to the presence of intranuclear inclusion bodies in infiltrating leukocytes (Figure 3g, h, i). The spleen showed lymphocytolysis, lymphoid depletion, and reticular hyperplasia. Prominent intranuclear eosinophilic inclusion bodies were observed in lymphocytes and reticular cells (Figure 3j, k, l).

**Virus detection by PCR**

Ten out of 50 examined flocks were positive for FAdVs (20%). Positive samples with a DNA length fragment of 590 bp were detected from cloacal swabs and liver tissues (Figure 4). The percentage of positive flocks from different governorates is listed in Table 2. In addition, all FAdVs positive samples were negative for IBDV and CIAV by -PCR.

Phylogenetic analysis
A phylogenetic tree was created based on our sequences, and the reference strain’s hexon gene sequences from different countries (Egypt, France, Brazil, Malaysia, China, Japan, and India) that were available on the GenBank (Table 3) to confirm the clustering of the various species. Phylogenetic analysis showed that the isolated FAdVs were classified as Fowl adenovirus type D serotype FAdV-2 and FAdV-11 in addition to Fowl adenovirus serotype FAdV-8a type E (Figure 5). Inter and intra-species analyses of genetic distance among the obtained sequences and other 14 aligned sequences available in the NCBI GenBank database of FAdV were performed (Figure 6). The genetic identity of FAdVs-type D had a high sequence homology (93.98% similarity) with the Indian FAdV type D, serotype 2 strains (MK816406.1 and MF770580.1) which previously has been isolated from liver tissues of broilers. On the other hand, the isolated FAdVs-type E viruses had a high sequence homology (99% similarity) with the Egyptian FAdV type E, serotype 8a (KT781516.1 and KT781517.1) that were isolated from cloacal swab samples of broiler chickens as illustrated in Figure 6. The partial hexon gene sequences of the two strains of FAdV-D and the FADV-E strain were submitted to the NCBI GenBank under accession numbers (MT386509.1, MT356630.1, MT893206.1, and MW847902), respectively (Table 3).

Virus isolation on cell culture
Three positive samples, including FAdV-D serotype 2, FAdV-D serotype 11, and FAdV-E (serotype-8a), were passaged on CEL. Different degrees of CPE on cell culture were observed in the inoculated cells as early as 24hr post inoculation after first passage with type E virus and after second passage from type D virus (Figure 7).

DISCUSSION

Over the past decade, inclusion body hepatitis–hydropericardium syndrome (IBH–HPS) has gained importance as one of the pivotal vertically transmitted diseases in broiler chickens that tackle the growing poultry industry all over the globe (Hafez, 2011; Shah et al., 2017; Schachner et al., 2018). In many countries, especially in Egypt, FAdvV is considered to be the main pathogen within the first five weeks of broilers causing significant economic losses (Radwan et al., 2019).

In the current study, the examined flocks grossly revealed hepatic enlargement with pale pinpointed foci, liver ecchymotic hemorrhage, and straw-yellow fluid in pericardium up to 15 mL. In addition, nephrosis and enlargement of the spleen were noticed. These lesions resemble IBH-HPS findings previously described by (McFerran and Smyth, 2000; Hafez, 2011).

These gross lesions and mortality were attributed to the replication of FAVS in liver cells and extensive hepatic damage which leads to a decrease in the colloid osmotic pressure and increase of blood vessel permeability with a massive accumulation of fluid around the heart and finally cardiac tamponade and death (Niu et al., 2019). Histologically, degenerative and inflammatory lesions were recorded in the intestine, liver, pericardium, and heart with the presence of eosinophilic intranuclear inclusion bodies similar to previous studies (Steer et al., 2015; Niu et al., 2019; Radwan et al., 2019c).

Although it was assumed before that the heart was not the target organ of FADV-4, severe pericarditis and heterophils infiltration were the most prominent lesions observed in the heart in the present study in addition to interstitial edema and widening of the gap between myocardial fibers (Niu et al., 2019).

Mortalities in the positive FAdvVs tested flocks had a wide range from 1 to 7.5%. Variation in broiler mortalities due to IBH was recorded in many countries including Canada (Ojkic et al., 2008), Japan, Iran (Rahimi and Minoosh Siavosh Haghighi, 2015), China (Changjing et al., 2016), and Egypt (Hafez, 2011; Radwan et al., 2019).

IBDV and CIAV have been reported as common co-infection of FAdvVs positive flocks which exacerbate the death rates as described by (Elbestawy et al., 2020). Despite this, there have been reports that IBH can cause mortality even when no other infective agent is present (Mohamed et al., 2018). Neither CIAV nor IBDV was detected in all FAdvVs positive flocks in the current study. Therefore, FAdvVs could be the primary pathogen responsible for mortality in the examined flocks.

Nevertheless, the clinical signs, post mortem lesions, and histopathology were highly indicative for FAdvV infection, molecular detection by PCR assay was used to confirm the disease as previously reported earlier by (Rau et al., 2005; Günes et al., 2012; Mittal et al., 2014). By using the conventional PCR technique, only 10 out of 50 examined flocks were positive (20%) and this low percentage of virus detection by PCR may be interpreted by the usage of a conventional PCR in viral recognition, which is less sensitive in comparing with a real-time PCR (Günes et al., 2012). Only three farms were positive for liver tissue samples, and seven farms were positive for cloacal swabs. Consequently, sampling by cloacal swabs is considered better than liver tissues for detection of FADV in broiler chicken, and this finding agrees with that recorded by (Radwan et al., 2019). In addition, FADV virus isolation was carried out using primary CEL and cytopathic effects were noticed after 24 hours of virus inoculation in the form of cell rounding and small focal cells’ areas detachment from the surface. Similar CPE in CEL of FAdvVs was previously described by (Soumyaleksomji et al., 2014; Mohamed Sohaimi et al., 2019).

Further typing of the isolated viruses indicated that they are belonged to FADV-type D serotypes 2 and 11, in addition to FAV- type E serotype 8a. The obtained sequences were clustered with fowl adenoviruses strains isolated from Europe, Brazil, Malaysia, China, Japan, and India. Many countries all over the world reported detection of FADV-D including Canada (Ojkic et al., 2008), South Africa (Maartens et al., 2014), China (Changjing et al., 2016), Poland (Niecyzporuk, 2016), Lebanon (Shaib et al., 2017), Saudi Arabia (Mohamed et al., 2018) and Egypt (El-Tholoth and Abou El-Azm, 2019; Elbestawy et al., 2020). In addition, Radwan et al., 2019 previously detected two strains of serotype FADV-8a (FADV-E) in Egyptian chicken farms during 2015. These viruses had a high sequence homology with the viruses isolated during the current study that throws light on the nature, and resistance of adenoviruses over time.

Detection and characterization of FAdvVs serotypes play a major role in epidemiologic studies of the disease spread, the development of preventative measures, and the application of vaccination programs. The current study spots light on the distribution and molecular characterization of FAdvVs from cases of IBH-HPS that have been recently increased in broiler chicken flocks in Egypt and resulted in significant economic losses to the poultry industry.

CONCLUSION

In conclusion, the necessity to update the recent situation of adenoviruses associated with hydropericardium syndrome in different broiler farms in many governorates in Egypt prompts us to conduct this study. Virus detection by PCR and sequence analysis indicated that both type D and type E adenovirus are the most common adenovirus associated with this syndrome in broiler farms in different governorates in Egypt. Further study will be conducted to study the pathogenicity of these isolated viruses in broiler chickens.
DECLARATIONS

Ethical considerations
Ethical issues including plagiarism, consent to publish, misconduct, data fabrication and/or falsification, double publication and/or submission, and redundancy have been checked by the authors.

Competing interests
The author has no conflict of interest.

Authors’ contributions
DGK, MGA, EAM, and GAA contributed to the design of the study, sample collection, isolation, identification of the virus, sequencing, and sequence analysis. MS carried out virus isolation, identification, and titration on cell culture. MSK carried out the histopathological examination. All authors drafted the manuscript and participated in the subsequent discussions and revisions of the entire text. All authors read and approved the results and final manuscript.

Acknowledgments
The authors would like to thank the Poultry diseases department, Faculty of Veterinary Medicine, Cairo University, Egypt for its assistance and support. This work did not receive any specific grant from any funding agencies.
